Abstract

The microbiota of four individual deep water sponges, *Lissodendoryx diversichela*, *Poecillastra compressa*, *Inflatella pellicula*, and *Stelletta normani*, together with surrounding seawater were analysed by pyrosequencing of a region of the 16S rRNA gene common to *Bacteria* and *Archaea*. Due to sampling constraints at depths below 700 m duplicate samples were not collected. The microbial communities of *L. diversichela*, *P. compressa* and *I. pellicula* were typical of low microbial abundance (LMA) sponges while *S. normani* had a community more typical of high microbial abundance (HMA) sponges. Analysis of the deep sea sponge microbiota revealed that the three LMA-like sponges shared a set of abundant OTUs that were distinct from those associated with sponges from shallow waters. Comparison of the pyrosequencing data with that from shallow water sponges revealed that the microbial communities of all sponges analysed have similar archaeal populations but that the bacterial populations of the deep sea sponges were distinct. Further analysis of the common and abundant OTUs from the three LMA-like sponges placed them within the groups of ammonia oxidising *Archaea* (*Thaumarchaeota*) and sulphur oxidising *γ-Proteobacteria* (*Chromatiales*). Reads from these two groups made up over 70% of all 16S rRNA genes detected from the three LMA-like sponge samples, providing evidence of a putative common microbial assemblage associated with deep sea LMA sponges.

Introduction

Marine sponges are important members of marine benthic communities throughout polar, tropical and temperate oceans. They are sessile filter feeding animals, capable of filtering up to 50 thousand litres of seawater per litre of sponge per day [1]. Marine sponges have gained much attention during recent years due to their remarkably dense and diverse community of bacterial, archaeal and eukaryotic microorganisms. This microbiota contributes to sponge biology in many ways, such as providing a chemical defence mechanism, carbon and nitrogen cycling and as a food source [2] [3]. Sponges can also be grouped according to the density of bacteria within their tissues into high microbial abundance (HMA) sponges and low microbial abundance (LMA) sponges [4] with HMA sponges reported to have microbial densities of 10^8 – 10^{10} bacteria per g of tissue while LMA sponges have 10^5 – 10^6 bacteria per g of tissue. Great efforts have been made to characterise the diversity of the microbial assemblages in shallow water sponges, and in HMA sponges in particular, using both culture dependent [5–8] and culture independent approaches [9–11]. Up to 2007, 15 bacterial phyla (including the candidate phylum *Poribacteria*), 2 major archaeal lineages and many microbial eukaryotes had been reported from marine sponges [2]. In recent years the application of “next generation” sequencing has allowed

access to the so called “rare biosphere” [12] and increased the number of bacterial phyla detected in sponges to more than 30. Marine sponges from the Great Barrier Reef [3], the Red Sea [13], the Mediterranean [14], the northern Atlantic [15,16], the Caribbean [17], Brazil [18] and worldwide [19] have been studied for their microbial diversity. More interesting than the sheer diversity of microbial communities which have been found in sponges are the presence of sponge-specific microorganisms, i.e. OTUs found almost exclusively in sponges [20]. In a comprehensive study of sponge-microbe associations, Schmitt *et al.* have distinguished between core, variable and species-specific assemblages in sponges. Interestingly, only a very small proportion of 90%, 95% and 97% OTUs was shared between different sponge species [19]. This “core” community of microbial OTUs found in most studied sponges implies a horizontal transfer of sponge-associated microbial diversity through the surrounding seawater. In previous studies, by comparison of larvae and adult sponges, evidence for vertical symbiont transfer has also been shown [3]. Thus potentially both vertical and horizontal transfer is involved in shaping sponge-associated microbial communities. Other studies have focused on describing the community structures in diverse sponges [3,15], including archaeal diversity [13], seasonal variations in the community structure [17] and functional analysis of the sponge metagenome [16,18].

Relative to their shallow water counterparts, little is known about the microbial diversity of deep water sponges, due in no small part to the inherent technical difficulties in obtaining specimens from below 1000 m. Nevertheless, in culture dependent studies Romanenko and co-workers reported the isolation of two new bacterial species from a deep sea sponge [21,22], while Brück and colleagues identified an *Entotheonella* species in *Discodermia dissoluta* from a depth of 150 m [23] and later characterized the culturable anaerobes from *Geodia* sp. samples from depths of ~200–350 m [24]. A culture independent study on *Polymastia cf. corticata* sampled at a depth of ~1100 m revealed that bacteria previously found in shallow water sponges are also present in deep water sponges and that the bacterial community has a spatial distribution in the sponge [25]; a phenomenon which has also been described for a shallow water sponge [26]. Deep water sponges, including a *Lissodendoryx* sp., [27,28] have also proven fruitful sources of novel bioactive compounds, many of which are likely to be of microbial origin.

The potential roles of most microorganisms within the sponge microbiota are, as yet, largely unknown. However recent studies using biochemical and metatranscriptomic approaches strongly suggest that ammonia-oxidising *Archaea* (AOA) are actively involved in nitrification within sponges [16,29]. Roles for other members of the sponge microbiota in processes such as sulphur oxidation and the provision of chemical defence systems are also likely but currently there is little direct evidence of these.

In order to increase our understanding of the microbial communities associated with deep water marine sponges and to assess potential similarities between the microbiota of deep water species, this study has applied the pyrosequencing approach to analyse the microbiome of sponge samples from the bathypelagic zone. Four northern deep water species, *I. pellicula*, *S. normani*, *L. diversichela* and *P. compressa* which have not previously been studied for their associated microbiota, were collected from deep water canyon systems in the North Atlantic at depths of 748, 1350, 1350 and 1469 m respectively. The primer pair targeting the V5–V6 region of 16S rRNA genes which is common between both *Archaea* and *Bacteria* was chosen because *Archaea* have been reported to be particularly abundant in deep water marine sponges [30]. Also, this primer pair yields sequence lengths of about 280 bp which enables the classification of sequence reads into lower taxonomic levels. The results of these analyses have led to the characterisation of the microbial communities associated with these sponge samples and the comparison of these communities has revealed a putative common microbial assemblage associated with deep sea LMA-like sponges. A fuller understanding of the deep sea sponge microbial community is a first step to understanding the roles these microbes play in this as yet poorly understood environment.

Results

Sponge sampling

Four sponge samples and water samples were obtained from depths of 700 m to 1500 m (Table 1). Sponge samples (Figure 1) were identified as *L. diversichela* (LD), *S. normani* (SN), *P. compressa* (PC) and *I. pellicula* (IP). Duplicate samples were not available for analyses due to the difficulties associated with sampling at such depths. The cortex and the choanosome of *S. normani* were processed as two separate samples in order to characterize any potential spatial distribution of bacteria in this sponge although for most analyses the data from these samples were combined. The outer layer of the sponge was cleaned carefully with a sterile scalpel in order to remove any sediment attached to the sponge.

Figure 1. Sponge samples *L. diversichela* (LD) and *S. normani* (SN).

doi:10.1371/journal.pone.0091092.g001

Taxonomic richness

A total number of 81,244 individual 16S rRNA sequence reads were obtained by pyrosequencing. Errors in the dataset were analysed and corrected using Acacia [31]. The average sequence length of all quality filtered sequences was ~280 bp. Following these quality checks a total of 70,582 sequences were analysed (Table 1) using QIIME [32]. Operational taxonomic units (OTUs) were selected at 97%, 94%, and 90% similarities and potentially chimeric sequences were removed using ChimeraSlayer following alignment. A total of 6,357 (97% similarity) OTUs were obtained from the sponge and water samples with 4,504 OTUs from the sponge samples alone (Table 2). The sample from sponge *Stelletta normani* had the most diverse population with 3,942 97% OTUs detected in this single sponge sample. The other sponge samples had OTUs ranging from 172 to 247, while OTUs in the water samples ranged from 382 to 1,213.

The rank abundance curves at 97% sequence similarity (Figure S1) show that the microbial communities of the samples from sponges *L. diversichela* and *I. pellicula* are dominated by a relatively small number of OTUs, demonstrated through the steep slope. The communities of the other samples are more evenly distributed with *S. normani* having the most even distribution. The rarefaction curve (Figure S2) of the microbial associates of the *S. normani* sample does not reach a plateau, indicating that even with over 22,000 reads there is an undersampling of the microbial biodiversity. The rarefaction curves of the other samples indicated that a greater proportion of the biodiversity was sampled although two of the water samples also indicated that there was some under sampling of these.

Bacterial vs. archaeal diversity

The relative abundance of archaeal reads in the sponge samples ranged from 4% in LD, 19% in SN, 48% in IP and up to 65% in PC, while in the accompanying surrounding seawater samples the *Archaea* made up 36–38% of all reads. *Archaea* were more often found in the cortex of the *S. normani* sample (28% relative abundance) than in the choanosome (10%). In all samples, bacterial reads made up the remaining proportion with a negligible amount of sequencing reads not classified into either of the two prokaryotic domains of life.

Archaeal diversity

In all sponge and water samples the two archaeal phyla *Euryarchaeota* and *Thaumarchaeota* were present (Figure 2). *Crenarchaeota* were detected at very low levels (two single reads) in two of the samples (W2 and W3). A total of 192 (97%) OTUs were classified as *Archaea*. Among the sponge samples there were 61 (97%) OTUs within the *Archaea* with the *Thaumarchaeota* being the most diverse *Archaea* present (46 OTUs). Over 95% of all archaeal reads in the sponge samples were *Thaumarchaeota* with the

The sponge and water samples were collected at depths from 700 m to 1500 m in canyon regions north of Porcupine Bank in the N. Atlantic.

*After applying Chimera Slayer from reads grouped into OTUs at 97% similarity.
doi:10.1371/journal.pone.0091092.t001

remainder classified as *Euryarchaeota*. The seawater samples contained both *Thaumarchaeota* and *Euryarchaeota* with the *Thaumarchaeota* fraction consisting of 17% (W-1), 62% (W-2) and 68% (W-3) of archaeal reads. Of the *Thaumarchaeota* fraction the vast majority of the seawater-derived reads and those from sponge IP were classified in the candidate genus *Nitrosopumilus*, whereas reads from the remaining sponges were mainly classified in the family *Cenarchaeaceae*. In each sponge sample over 70% of the *Thaumarchaeota* fraction was made up of up to three (97%) OTUs. Among reads classified as *Euryarchaeota* there were no abundant OTUs from the sponge samples, with the water samples each containing several OTUs in the marine group II and III *Thermoplasmata*.

To allow further analysis of the archaeal members of the sponge associated communities, longer fragments of the archaeal 16S rRNA genes were amplified and cloned. Each of these sponge libraries was found to contain clones that were close matches to abundant amplicons from the respective pyrosequencing libraries. All the archaeal 16S rRNA gene sequences recovered from the clone libraries were analysed by BLAST analysis and by taxonomic classification with Greengenes, RDP and Silva pipelines. Phylogenetic analysis (Figure 3) and Greengenes taxonomy (Table 3) showed that all sponge archaeal clones grouped with the Marine Group I *Thaumarchaeota*. Phylogenetic analysis revealed two distinct clades; a clade of sponge-derived reads from sponges *I. pellicula*, *P. compressa* and *S. normani* that clustered together with *Nitrosopumilus maritimus* and the sponge symbiont *Cenarchaeum symbiosum*; and a clade consisting of clones from sponges *L. diversichela* and *P. compressa* that clustered with seawater-derived archaeal reads (Figure 3).

Bacterial diversity

A total of 6,160 bacterial OTUs were detected at 97% similarity with 4,506 bacterial OTUs (97%) present within the sponge reads (Figure 4). These OTUs were assigned to a total of 35 bacterial phyla (including candidate phyla) with 28 phyla detected in the sponge-derived reads. The most diverse phylum of bacteria within the sponge samples were the *Chloroflexi* with 1,487 individual OTUs (97%) present (this was reduced to 118 OTUs when sequences were grouped at 90% sequence similarity), the *Proteobacteria* were the next most diverse phylum with 722 OTUs (97%). The proteobacterial OTUs could be further subdivided into 317 γ -*Proteobacteria*, 128 δ -*Proteobacteria* and 167 α -*Proteobacteria*. Other diverse groups of bacteria present included the *Acidobacteria* with 321 OTUs (97%), the *Poribacteria* with 114 OTUs (97%), the *Actinobacteria* with 110 OTUs (97%), *Gemmatimonadetes* with 54 OTUs (97%) and *Bacteroidetes* with 48 OTUs (97%). A large number of 97% OTUs (1297) were classified only at the domain

level but these were conflated to 234 when a 90% similarity cut off was used. A summary of OTU numbers at different similarity groupings is shown in Table 2.

A number of candidate divisions/Phyla were also detected in addition to the *Poribacteria*; GN02, OP3, SAR406, TM7, and ZB3 were all detected with low read abundance and diversity, with candidate divisions/Phyla SBR1093 and WS3 being more diverse (23 OTUs (97%) and 25 OTUs (97%) respectively) in the sponge samples.

Analysis at lower taxonomic levels

Analysis at lower taxonomic levels revealed that the *Thaumarchaea* present in all sponges were classified in the genera *Cenarchaeum* and *Nitrosopumilus* (Figure 3). From genomic analysis of the sponge symbiont *Cenarchaeum symbiosum* and physiological studies of cultured *Nitrosopumilus* these species are known to belong to the group of ammonia-oxidising archaea (AOA) capable of oxidising ammonia to nitrite [33–35]. Other microorganisms present within the sponges with potential contribution to nitrogen cycling are the nitrite oxidising bacteria *Nitrospiraceae*, *Nitrospina* and the ammonia oxidising bacteria *Nitrosomonadales*. Reads classified to *Nitrospira* were found in three of the sponge samples though they were more prevalent in SN and IP, whereas *Nitrospina* classified reads were found in all sponge samples.

Of the other common phyla detected within the sponges *Acidobacteria* group 6, and *Chloroflexi* SAR202 were found in all sponge samples and were especially common in SN (Figure 3). These groups are typical members of the sponge microbiota and have been found in numerous studies of sponges from diverse habitats including sponges from shallow, tropical environments [13] and from deeper, cold water environments [16]. However all sponge samples contained OTUs consisting of large numbers of reads that were classified only at the level of the class γ -*Proteobacteria*. When the data was analysed at 90% similarity grouping, many of these OTUs grouped together to form single OTUs.

As these unclassified γ -proteobacterial reads appeared to represent an abundant OTU within the sponges we sought to study these in greater detail. To allow for more robust phylogenetic analyses than are possible with the shorter reads generated by pyrosequencing near full length 16S rRNA libraries were prepared from each sponge metagenome with several clones (4–30) sequenced from each. Comparison to the pyrosequencing data showed that each of these small libraries contained representative clones of the most common OTUs detected in the pyrosequencing data (including unclassified γ -*Proteobacteria*, *Nitrospira*, *Chloroflexi* and others). These sequences were analysed further

Number of OTUs and species richness estimates of the seawater and sponge-associated microbial communities. Chao1 and Shannon indices were determined at 97, 94 and 90% similarities of 16 s rRNA sequences. doi:10.1371/journal.pone.0091092.t002

by BLAST analysis, by taxonomic assignment using RDP, Greengenes and Silva pipelines and by alignment and phylogenetic analyses. Greengenes taxonomic assignment classified the previously unclassified γ -proteobacterial OTUs within the *Chromatiales* or with sulphur oxidising symbionts (Table 3). Likewise phylogenetic analysis of these clones showed that all these 16S rRNA sequences were found to cluster within the *Chromatiales* group of γ -*Proteobacteria* together with other sponge-derived sequences and endosymbionts from tubeworms (Figure 5). All cultured members of these groups and characterised symbionts are believed to be involved in sulphide oxidation [36–38]. Other sequenced clones confirmed the presence of multiple *Chloroflexi* from *S. normani*, *Nitrospira* and *Nitrospina* bacteria together with other groups detected from the pyrosequencing analysis (*Acidimicrobiales*, *Gemmatimonadetes* and *Acidobacteria*).

Analyses of sponge communities

Robust comparison of sponge species specific microbial communities was not possible due to the lack of duplicate sponge samples, however shared features of the deep sea sponge microbial communities were examined. In order to determine whether there was a shared deep-sea sponge microbial community the compositions of the sponge microbial communities were analysed by direct comparison of shared OTUs. Classified reads were first grouped into OTUs at 97%, 94% and 90% sequence similarity, OTUs shared between sponge samples were then analysed to determine if there was a common microbiota. For the purposes of this study the shared microbiota was defined as OTUs that were present in at least 3 of the 4 sponge species analysed (Table 4).

At all sequence similarity groupings (90%, 94% and 97%) over 70% of all OTUs were present within just a single sponge sample. At 97% similarity grouping there were very few shared OTUs with only 3 OTUs shared between 3 or more sponge samples, and 25 present in 2 or more. The analysis of shared OTUs at 94% similarity gave 23 OTUs that were present in 3 or more sponge samples and at 90% similarity there were 37 OTUs present in 3 or more sponge samples (Table 4). While the number of OTUs shared between the sponge samples was low compared to the overall number of OTUs present, when the number of reads associated with the shared OTUs were analysed it was found that the common microbiota (at 90% OTU similarity) comprised 25% (SN), 86% (IP), 87% (PC), and 95% (LD) of the total number of analysed reads for each sponge sample. The microbiota of the sponge and seawater samples was also compared using UniFrac UPGMA cluster analysis. The relationship between the samples shows that the three water samples from the different depths and locations have similar microbial communities and form a cluster (Figure 6). The sponge samples clustered into two groups, one consisting of the choanosome and cortex from the two samples of SN and the other cluster consisting of the microbiota of IP, PC and LD. Thus the microbial communities of the two tissue types from the *S. normani* sample are highly similar as are the communities from the single samples of sponges *I. pellicula*, *P. compressa*, and *L. diversichela* (Figure 6).

The shared microbiota was found to contain 3 OTUs (90%) classified as *Thaumarchaeota* (also in Figure 3) comprising a total of over 95% of all reads characterised as *Archaea*. In addition the shared microbiota was found to contain an OTU within the group of γ -*Proteobacteria* described above as grouping with the *Chromatiales*. This OTU comprised 69%, 41% and 90% of the bacterial reads from IP, PC and LD respectively. A related OTU within the *Chromatiales* group (identified by BLAST and phylogenetic analysis) from SN comprised 6% of the bacterial reads from this sponge sample (Figure 5). While the common sponge community

doi:10.1371/journal.pone.0091092.g004

described above accounted for over 75% of all reads in sponge samples from IP, PC, and LD, the SN sponge sample had a more complex community with the presence of many reads classified as *Acidobacteria*, *Poribacteria*, *Chloroflexi*, *Nitrospira* and candidate SBR1093 (Figure 3). The high diversity and overall makeup of the microbial community of the SN sample is similar to that found in high microbial abundance (HMA) sponges from other marine environments [39] and this data clearly supports the classification of SN as a deep water HMA sponge. In contrast, the dominance of IP, PC and LD by a few OTUs is typical of low microbial abundance (LMA) sponges [40] and these three sponge samples are likely to be examples of deep sea LMA sponges.

Comparison to other sponge communities

To compare the microbial communities of the deep sea sponges that were the subject of this study with other sponge microbial communities the dataset from a study of sponges collected from the Red Sea at depths of 8–19 m was analysed [13]. These data were generated using the same primer pairs as used in this study so a direct comparison of the data was possible. The Red Sea sponge data were reanalysed together with the deep sea data.

Comparison of shared OTUs grouped at 90% similarity indicated that there were similarities in the archaeal communities (Table 5). One archaeal OTU, classified as *C. symbiosum* was present in all samples making up a large proportion (20–98%) of all reads classified as *Archaea*, while two other OTUs classified as *Archaea* were detected in 6 of the 7 sponge samples. These three common archaeal OTUs together accounted for 65–99% of total archaeal reads (Table 5A). One bacterial OTU, classified as *Acidobacteria-6*, was found in all samples, however the abundance of these reads was low (<0.1%) in three of the sponge samples. Five other bacterial OTUs were found in 6 of the 7 sponge samples,

however all these shared bacterial OTUs made up only 1–7% of the total reads (Table 5A). In contrast, analysis of the Red Sea shallow water sponges revealed 103 shared OTUs in total, 6 archaeal OTUs and 97 bacterial OTUs, together these shared OTUs constituted 82–93% of the archaeal reads and 63–79% of the bacterial reads from the Red Sea shallow water sponges indicating a high degree of similarity in the microbial communities of these sponges (Table 5B). Of the 97 bacterial OTUs common to the Red Sea shallow water sponges, only 7–11 were present in the deep sea LMA sponges and these made up 1–23% of the total bacterial reads (Table 5B). A total of 27 OTUs were found to be common to the deep sea LMA sponges, 5 archaeal and 22 bacterial. These shared bacterial OTUs made up a total of 67–94% of the deep sea bacterial reads (Table 5C). Of the bacterial OTUs common to the deep sea LMA sponges, 3–14 were also detected in the Red Sea shallow water sponges, however these were found to make up only a small component (2–5%) of the bacterial population of the Red Sea sponges, highlighting differences in the microbial community structures.

The microbial communities of deep sea and Red Sea shallow water sponges were also analysed using UniFrac UPGMA cluster analysis (Figure 7). The results of this largely supported the analysis of the shared OTUs, the microbiota of the three LMA-type deep water sponges (LD, IP and PC) were found to be more similar to each other than to other sponge or water samples with the microbiota of the LMA Red Sea sponge *Syllissa carteri* being more closely related than other sponge or water samples. The microbiota of SN was found to be more distinct but again was more related to the microbiota of the Red Sea sponges *Xestospongia testudinaria* (a confirmed HMA sponge) and *Hyrtios erectus* (a presumed HMA sponge). The UniFrac analysis thus supports the classification of the sponges LD, IP and PC as LMA and SN as HMA.

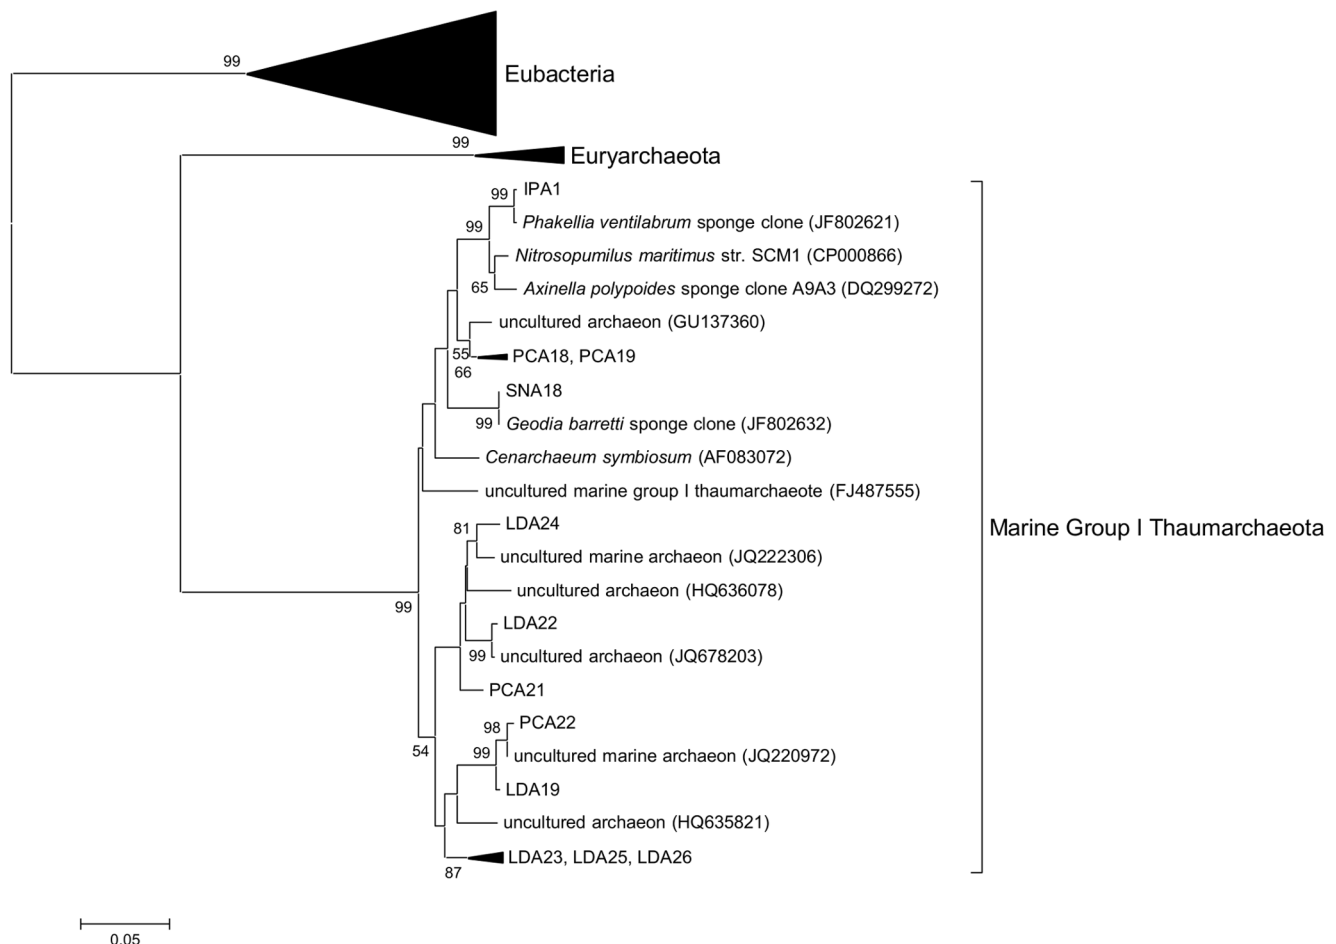

Figure 5. Phylogenetic relationship of bacterial 16S rRNA clones from deep sea sponges. 16S rRNA sequences were determined from cloned PCR amplicons (also see Table 3). Sequences were aligned using PyNast and neighbour joining phylogenetic tree was constructed using MEGA5. One representative sequence per OTU was used for alignment and construction of tree. Bootstrap values (500 replicates) greater than 50% are shown next to the branches.

doi:10.1371/journal.pone.0091092.g005

Discussion

Marine sponges have long been known to harbour a wide range of microbes and while the microbial community of shallow water sponges has been studied extensively, relatively little is known about the microbes associated with deep water sponges, especially from the bathypelagic and deeper zones. By applying the 454 pyrosequencing approach to assess the microbial communities of deep-water sponge samples this study sheds further light on microbes associated with these sponges.

Bacterial community

The lack of duplicate sponge samples in this study means that robust conclusions about the microbial communities associated with individual deep seawater sponge species are not feasible. However the shared microbiota of these deep sea sponge species has been analysed to determine whether there is a specific microbial community associated with deep water sponges. The analysis of shared OTUs between the deep sea sponge samples revealed that most of the OTUs present were unique to individual sponge samples, however there was also a number of OTUs that were shared between at least 3 of the 4 deep water sponge species investigated, suggesting a shared core community in these deep

water sponges. Although sequence abundance can not be considered truly quantitative due to biases in PCR amplification and differences in 16S rRNA gene copy number these OTUs were found, in some cases, to constitute very large proportions of the total reads in the study, indicating that they are likely to make up substantial parts of the sponge microbial communities. Analysis of pyrosequencing read abundance has proved insightful in a recent study describing and demonstrating differences in microbial-host specificity in LMA sponges [41]. Microbes within these abundant groups included the AOA *Thaumarchaeota*, a group which contains the sponge symbiont *C. symbiosum*. A second group of microbes present in all sponge samples were identified as γ -*Proteobacteria* within the *Chromatiales* group. In three of the sponge samples IP, LD and PC these two microbial groupings made up over 70% of all reads. This lower diversity microbial community is typical of low-microbial abundance (LMA) sponges, however other studies of LMA sponges have concluded that each sponge species harbours a unique bacterial community [40], while the data here suggest a potential common microbiota for deep sea LMA sponges. The data from this study also confirm other recent reports that LMA sponges have microbial communities that are distinct from and are not merely a reflection of surrounding seawater [40,41]. Direct comparison of pyrosequencing data, including shallow water LMA

Table 4. Analysis of OTUs shared between deep sea sponge samples.

OTU similarity grouping	<i>S. normani</i>		<i>L. diversichela</i>		<i>I. pellicula</i>		<i>P. compressa</i>	
	Shared OTUs	% of reads	Shared OTUs	% of reads	Shared OTUs	% of reads	Shared OTUs	% of reads
97%	2	0.02%	4	3%	3	0.1%	3	1.5%
94%	13	4%	22	93%	20	86%	20	71%
90%	24	25%	36	95%	37	86%	32	87%

OTUs were determined at 97, 94 and 90% similarities. OTUs were considered to be shared if present in three of the four sponges. The proportion of the total reads made up of the shared OTUs is indicated.

sponges, with this dataset revealed that the microbial communities of all the sponges have similar archaeal populations but that the bacterial populations of the deep sea sponges are distinct. Other non-pyrosequencing based studies of LMA sponges collected from shallow temperate and tropical waters show that LMA sponges typically have a single large bacterial OTU that can be cyanobacterial or proteobacterial, and that appears to be species specific [40]. This is in contrast to the deep sea LMA sponges which, from the data presented here, appear to have a more conserved bacterial population structure. Two additional studies of deep sea sponge microbiota provide additional support for this; analysis of the microbial community of a single sample of a deep sea *Polymastia* sponge by DGGE analysis of 16S rRNA genes and *aprA* (adenylyl-sulphate reductase) genes revealed the presence of sulphur-oxidising γ -*Proteobacteria* (*Chromatiales*) and marine group I *Thaumarchaeota* [25]. Likewise in another study bacterial 16S rRNA genes amplified from two individual deep sea sponge samples were analysed by DGGE and the dominant bands were shown to be derived from thioautotrophic γ -*Proteobacteria* [37]. These studies, together with the deeper pyrosequencing data presented here provide additional evidence for a common microbial community structure in deep sea sponges.

AOA have previously been shown to be transcriptionally and metabolically active in nitrification in cold water sponges [16,29] and nitrification has also been detected in LMA sponges [42], thus it seems likely that the AOA groups detected in these sponges may have similar metabolic capabilities. The other abundant group, thioautotrophic γ -*Proteobacteria* has previously been found within sponges [11,37], and associated with other marine invertebrates such as marine tubeworms and shellfish [38]. This class of bacteria appears to be a frequent symbiont, present in many marine invertebrates. Analysis of the seawater derived sequences revealed that at the 90% similarity threshold these γ -*Proteobacteria* were essentially absent from seawater with a single read from one seawater sample grouping into the shared OTU. While it is possible that these bacteria are acquired from seawater they are clearly concentrated within the sponge tissue and appear to dominate the microbial communities of several sponge species. The SN sponge sample has a microbiota more typical of high-microbial abundance (HMA) sponges, with many bacterial species present and typical phyla such as *Nitrospira*, *Acidobacteria*, *Poribacteria* and *Chloroflexi* being observed. However this sponge also appears to have some similarities with the other deep water sponges under study; namely the presence of a common *Thaumarchaeota* OTU and a *Chromatiales* OTU, which together make up 19% of all reads in SN.

Table 5. Analysis of OTUs shared between deep sea sponges and Red Sea sponges.

		Red Sea Sponges				Deep Sea Sponges			
		<i>X. testudinaria</i>	<i>H. erectus</i>	<i>S. carteri</i>		<i>S. normani</i>	<i>L. diversichela</i>	<i>P. compressa</i>	<i>I. pellicula</i>
		(HMA)	(HMA)	(LMA)		(HMA)	(LMA)	(LMA)	(LMA)
	OTUs	% of reads	% of reads	% of reads		% of reads	% of reads	% of reads	% of reads
	OTUs	OTUs	OTUs	OTUs		OTUs	OTUs	OTUs	OTUs
A	Shared OTUs: Archaea	3	65%	2	74%	2	68%	3	94%
	Bacteria	5	4%	6	3%	5	5%	5	1%
B	Shared OTUs: Archaea	6	93%	6	91%	1	82%	1	78%
	Bacteria	97	76%	97	63%	34	79%	8	1%
C	Shared OTUs: Archaea	3	65%	2	74%	4	68%	5	99%
	deep sea LMA Bacteria	3	3%	14	2%	6	5%	22	67%
	sponges							22	73%

OTUs were determined at 90% similarity. For Row A OTUs were considered shared between all sponges if present in 6 of the 7 sponges. For Rows B and C OTUs were considered shared if present in all 3 of the Red Sea shallow water sponges or deep sea LMA samples respectively. Figures in the table indicate the total number of OTUs shared in each class for each sponge and the % of archaeal or bacterial reads these OTUs encompassed.

Evidence of a deep sea specific sponge community?

The role of these *Archaea* and *Bacteria* within deep sea sponges is unknown, however the presence of two groups of microorganism whose closest studied relatives are chemolithoautotrophic is striking. The *Thaumarchaeota* are AOA, gaining energy through oxidation of ammonia while the sulphur oxidising *γ-Proteobacteria* gain energy through oxidation of sulphide and other sulphur compounds. As previously mentioned, AOA have been shown to be major contributors to nitrification in cold water sponges and in the sponge *Geodia barretti* archaeal transcripts predicted to be involved in ammonia oxidation are highly abundant [16]. A symbiotic relationship between marine tubeworms and sulphur oxidising bacteria is well established, with tubeworms dependent on nutrients supplied by sulphur oxidising chemoautotrophic *γ-Proteobacteria* [43]. A similar role for sulphur oxidising bacteria within sponges has not been shown although these bacteria appear to be widespread and abundant in deep sea sponges [37,38]. There is also a report of a specific putative symbiosis between free-living marine *Thaumarchaeota* and sulphur-oxidising *γ-Proteobacteria* in sulphide rich mangrove swamps [44], implying that these two organisms themselves can form a close symbiotic relationship. How these common chemolithoautotrophic microorganisms contribute to the physiology of deep sea sponges is as yet unknown but their consistent presence implies a potentially important symbiotic relationship.

Conclusion

This study presents an analysis of the shared prokaryotic diversity of four individual deep-water sponges and shows that the microbiota of these deep-water sponges share features with their shallow water counterparts. All sponge samples were found to contain diverse *Bacteria* and *Archaea*, and among the *Archaea* present a group classified as *C. symbiosum* was present in all samples. Three

of the individual sponges in the study *L. diversichela*, *I. pellicula* and *P. compressa* were classified as LMA sponges on the basis of their microbial communities. The microbial composition of the *S. normani* sample includes many OTUs from groups commonly found in HMA marine sponges. Pyrosequencing data indicated that the LMA sponges *L. diversichela*, *I. pellicula* and *P. compressa* were dominated by two microbial groups; AOA *C. symbiosum* group and sulphur-oxidising γ -*Proteobacteria*, providing evidence of a putative common deep sea LMA sponge microbial community consisting of ammonia oxidising *Archaea* and sulphur oxidising γ -*Proteobacteria*. The data presented here are derived from four individual sponge samples and additional data will be required to determine if this apparent deep sea LMA sponge microbial community is shared with other deep sea sponges. Due to the nature of the current study the contribution of these common and apparently abundant members of the deep-sea sponge community to the shared metabolism of the sponge community is unknown but it is likely that these abundant microbes play an important role in sponge biology.

Methods

Sample collection

Specific permission was not required, to obtain the marine sponge samples used in this study as they were collected in Irish territorial water, by an Irish research vessel, funded by the Irish government. The sponge samples do not involve endangered or protected sponge species. The sponge samples used in this study were collected with the remotely operated vehicle (R.O.V.) *Holland I* during the Biodiscovery cruise 2010 aboard R.V. *Celtic Explorer*. Upon retrieval the sponge samples were washed with sterile, artificial seawater (33.3 g/L Instant Ocean, Aquarium Systems – Blacksburg, VA, USA) and stored at -80°C until molecular work was carried out in our laboratories in Cork. A part of each sample was also used for taxonomic identification by Christine Morrow, Queens University, Belfast. Additionally, a water sample was retrieved during a CTD (Conductivity-Temperature-Depth) measurement. 30 L water were collected as close as possible to the sponge sampling site, filtered through a $0.2\ \mu\text{m}$ membrane filter (Whatman – Austin, TX, USA) and the filter was immediately frozen at -80°C . Depths and GPS location of samples are indicated in Table 1. Duplicate samples were not collected due to sampling difficulties at such depths.

Metagenomic DNA extraction from seawater and sponge samples

DNA was extracted from filters using WaterMaster DNA Purification Kit (Epicentre Biotechnologies, Madison, WI, USA) according to the manufacturer's instructions. Extracted DNA was stored at -20°C .

The sponge tissue (3–5 g) was cut into fine pieces with a sterile razorblade and then ground to a fine powder under liquid nitrogen using a mortar and pestle. For the *S. normani* sample, the cortex was first separated from the choanosome, cleaned carefully with sterile artificial seawater and any remaining sediment from the surface was removed with a sterile razor blade. For the choanosome a cross section of the ball shaped tissue was taken in order to include inner- and outer areas of the choanosome. While processed separately reads from choanosome and cortex were ultimately pooled for some analyses. The ground sponge tissue was added to a lysis buffer adapted from Brady (100 mM Tris, 100 mM EDTA, 1.5 M NaCl (w/v), 1% CTAB (w/v), 2% SDS (w/v); 5 ml buffer per 1 g sponge tissue; [45]) and incubated for 2 h at 70°C . Metagenomic DNA was then extracted as previously

described [11]. DNA solutions were analysed by gel electrophoresis, quantified by spectrophotometry (NanoDrop ND-1000-Wilmington, DE, USA) and then stored at -20°C .

PCR amplicon library preparation for pyrosequencing

PCR amplicon libraries of the V5–V6 region of 16S rRNA genes were prepared from all metagenomic DNAs. Universal primers U789f (5'-TAGATACCCSSGTAGTCC-3') and U1068r (5'-CTGACGRCRGCCATGC-3'), targeting both bacteria and archaea [13], were adapted for pyrosequencing by the addition of sequencing adapters and multiplex identifier (MID) sequences as per Table S1. Each 50 μl PCR reaction comprised 1 \times buffer, 0.2 mM dNTPs (both Fermentas, St. Leon-Rot, Germany), 0.1 μM of each primer (Sigma Aldrich, Arklow, Ireland), 2 U Taq polymerase (Fermentas), ~ 10 ng template DNA and dH_2O . PCR cycle conditions were as reported previously [13]. To minimise PCR bias three individual reactions were performed per template and equimolar amounts of PCR products from each of the three reactions were pooled for pyrosequencing. PCR products were purified using Qiagen PCR Purification Kit (Qiagen Ltd., UK) as per the manufacturer's instructions. Barcoded samples were pooled and sequenced on a GS FLX Titanium platform (454 Life Sciences) at the University of Liverpool, Centre for Genomic Research, Liverpool, UK.

Pyrosequencing data analysis

Initial quality filtering and barcode assignment of reads was performed using the QIIME package [32]. Sequences shorter than 200 nucleotides, with an average quality score <25 , or with >6 ambiguous bases were removed from the analysis. All reads were then analysed for errors and corrected using Acacia1.52 [31]. Reads were then grouped into OTUs at 97%, 94% and 90% sequence similarities using uclust. Each OTU was then assigned to a taxonomic group using the RDP classifier at 50% confidence and the Greengenes database of assigned sequences [46]. OTUs were then aligned to the pre-aligned Greengenes 16S data using PyNAST [47]. Potentially chimeric sequences were identified and removed from the dataset using ChimeraSlayer [48].

Rarefaction and rank abundance curves were calculated from OTU tables generated at 97% similarity using alpha diversity and rank abundance scripts within the QIIME pipeline. Shannon indices and Chao1 species estimators were calculated from OTU tables generated at 90%, 94% and 97% similarity using alpha diversity scripts within the QIIME pipeline.

Raw sequences are deposited in MG-RAST [49] and the NCBI short read archive with the following MG-RAST ID and BioSample numbers; IP – 4533583.3, SAMN02402455; LD – 4533578.3, SAMN02402456; PC – 4533577.3, SAMN02402457; SNCh – 4533579.3, SAMN02402458; SNC0 – 4533580.3, SAMN02402459; W-1 – 4533582.3, SAMN02402460; W-2 – 4533576.3, SAMN02402461; W-3 – 4533581.3, SAMN02402462.

Cloning and analyses of near full length 16S rRNA genes

To generate longer sequences, suitable for more detailed phylogenetic analyses 16S rRNA genes were amplified from sponge metagenomic DNAs using primer sets 27f/1492r for eubacterial 16S rRNA genes [50] and Arch21F/Arch958R for archaeal 16S rRNA genes [51]. PCR amplicons were cloned into pJET1.2 (Thermo Scientific) and a selection of clones from each library were sequenced. Each of these libraries was found to contain sequences that were near-identical ($>99\%$) to the most abundant reads in the V5–V6 libraries. Sequences were trimmed and aligned using PyNast [47] and analysed for chimaeras using ChimeraSlayer [48]. Phylogenetic trees were then calculated in

MEGA5 [52] using Neighbour-joining [53] and Maximum likelihood [54] algorithms. Near full length 16S rRNA sequences of clones from this study have been deposited at GenBank with accession numbers KF597097–KF597136.

Table S1 Primer design including Multiplex Identifier (MID). (DOC)

Acknowledgments

We thank Dr. Christine Morrow, Queen’s University Belfast for the identification of sponge samples and Dr Louise Allcock, Chief Scientist aboard survey CE10004 of Celtic Explorer to the Irish continental margin for facilitating the collection of samples, and thank the captain and crew of Celtic Explorer and participating scientists for their assistance.

Author Contributions

Conceived and designed the experiments: JK BF SAJ JPM FOG ADWD. Performed the experiments: BF SAJ. Analyzed the data: JK BF ADWD. Wrote the paper: JK BF ADWD.
